

Efimov Trimer Formation via Ultracold Four-body Recombination

Yujun Wang and B.D. Esry

Department of Physics, Kansas State University, Manhattan, Kansas 66506, USA

We discuss the collisional formation of Efimov trimers via ultracold four-body recombination. In particular, we consider the reaction $A+A+A+B \rightarrow A_3+B$ with A and B ultracold atoms. We obtain expressions for the *four*-body recombination rate and show that it reflects the *three*-body Efimov physics either as a function of collision energy or as a function of the two-body s -wave scattering length between A atoms. In addition, we briefly discuss issues important for experimentally observing this interesting and relatively unexplored process.

PACS numbers:

The exquisite experimental control possible in ultracold atomic gases has enabled the observation of unique and bizarre quantum states. For instance, the many-body phenomena of Bose-Einstein condensation [1, 2] and Fermi degeneracy [3, 4] have both been observed and used for a wide range of studies [5, 6]. Weakly-bound diatomic Feshbach “halo” molecules have also been observed [7] and their dynamics probed [8]. Especially relevant to the present work, the Efimov effect [9] was finally confirmed experimentally via three-body recombination of cesium atoms [10]. This experimental observation of Efimov physics was preceded by a considerable amount of theoretical work due to its general importance for ultracold three-body collisions (see, for instance, Refs. [11, 12, 13, 14]), and we now have a remarkably complete characterization of these processes.

Our goal for this Letter is to examine four-body collisions in an ultracold two-component gas. In particular, we want to explore the possibility of producing Efimov trimers via four-body recombination. Since the experimental evidence for the Efimov effect is from low-energy three-body collisions rather than from bound trimers, producing the trimers is a natural next step. One scheme for doing this in the tight confinement of an optical lattice has been proposed [15], but here we investigate one possibility for producing them in free space.

Besides the intrinsic interest of Efimov states, it is also important to develop the theory of the fundamental process of four-body recombination quantum mechanically. Compared with three-body collisions, our knowledge of ultracold four-body collisions is still quite rudimentary. The reason is clear: solving the Schrödinger equation with three additional degrees of freedom is a much more difficult task. There have, of course, been many studies of four-body systems, but only recently have some relevant to ultracold quantum gases begun to appear [16, 17, 18, 19] — none of which have addressed four-body recombination.

The system we consider in this Letter is an ultracold mixture of atoms A and B . We take A to be bosons, but all we need specify now about B is that they are distinguishable from A . Our goal is to produce Efimov

trimers A_3 via the four-body recombination process

To this end, we will assume that the two-body s -wave scattering length among A atoms a_{AA} is infinite to give the most favorable case for Efimov states. We will also assume that the interspecies scattering length a_{AB} is finite and that any dimer states, which are likely to be present in real systems, lie much deeper than the weakly bound Efimov trimer states.

Our treatment of this process is asymmetrical in A and B , mirroring the differences in their relative scattering lengths. The two-body interactions for the A_3 subsystem are well-described by the zero-range model [9]. The advantage of this model is that the three-body solutions are known and especially simple in the $|a_{AA}| \rightarrow \infty$ limit [9]. Note that extending this model to four-body systems leads to equations that are not straightforward to solve. Instead, we borrow an idea from Rydberg physics [20, 21] — and from many-body theories of Bose-Einstein condensates (BECs) as well [22] — to model the AB interaction. Since the wavelength of the A atoms, either when they are free or in the Efimov molecule, is much larger than the size of atom B , the AB interactions can be approximated by the Fermi contact potential [23] (atomic units will be used throughout)

$$V_{AB}(r_{i4}) = \frac{2\pi a_{AB}}{\mu_{AB}} \delta(r_{i4}), \quad i = 1, 2, 3, \quad (2)$$

where μ_{AB} is the two-body reduced mass and r_{i4} is one of the AB interparticle distances. The Jacobi coordinates we use to represent the internal motion of the four particles are shown in Fig 1.

Given the success of the adiabatic hyperspherical representation in describing the three-body continuum [11, 12], we will use it here to treat the four-body continuum as well. Since we want to use the known solutions for the A_3 subsystem, we build the four-body hyperspherical coordinates from the three-body ones [24]. The four-body hyperradius R_4 and hyperangle α_4 are thus defined as

$$\mu_4 R_4^2 = \mu_{3,4} \rho_3^2 + \mu_3 R_3^2 \quad \text{and} \quad \tan \alpha_4 = \sqrt{\frac{\mu_3}{\mu_{3,4}}} \frac{R_3}{\rho_3}. \quad (3)$$

FIG. 1: The Jacobi coordinates for the four-body system. Atoms 1, 2, and 3 are identical bosons A with mass m_A , while atom 4 is an atom of another species B with mass m_B .

Here, $\mu_3 = m_A/\sqrt{3}$, $\mu_{3,4} = 3m_A m_B / (3m_A + m_B)$, and $\mu_4 = \sqrt{\mu_3 \mu_{3,4}}$. Finally, R_3 denotes the three-body hyper-radius; and α_3 , Delves' three-body hyperangle [24].

The representation we will use for the four-body problem, however, is not fully adiabatic in that we will not include the interactions V_{AB} in the adiabatic Hamiltonian H_{ad} . Rather, we will include them later as coupling between the channels. This choice, together with our definition of coordinates, permits separation of variables in the adiabatic equation, utilizing the known solutions for the A_3 subsystem. Mathematically, this procedure begins with the four-body Schrödinger equation

$$[T_{R_4} + V_{AB}(r_{14}) + V_{AB}(r_{24}) + V_{AB}(r_{34}) + H_{\text{ad}}] \Psi = E \Psi,$$

where T_{R_4} is the hyperradial kinetic energy and

$$H_{\text{ad}} = T_{\Omega_4} + T_{\Omega_3} + V_{123}, \quad (4)$$

which includes the hyperangular kinetic energies T_{Ω_i} as well as all of the interactions among A atoms in V_{123} . The notation Ω_3 denotes collectively all of the three-body hyperangles; and Ω_4 , all remaining hyperangles for the four-body system. In the ultracold limit, only the zero total orbital angular momentum solution is relevant by the generalized Wigner threshold law [25]. And, since Efimov states only exist for zero orbital angular momentum of A_3 , the angular momentum of B relative to the trimer must also be zero. The channels for the four-body problem are thus defined from

$$H_{\text{ad}} \Phi_\nu^{(4)} = U_\nu(R_4) \Phi_\nu^{(4)}. \quad (5)$$

Separation of variables allows ($\nu \equiv \{\alpha, n\}$)

$$\Phi_\nu^{(4)}(R_4; \Omega_4, \Omega_3) = u_{\alpha n}(R_4; \Omega_4) \Phi_\alpha^{(3)}(\Omega_3). \quad (6)$$

Because we have chosen $a_{AA} \rightarrow \infty$, $\Phi_\alpha^{(3)}(\Omega_3)$ does not depend on R_3 — otherwise this separation would only be approximate and the resulting equations would have to be solved numerically. For four-body recombination, we will need to find not only the $A_3 + B$ bound channels, but also the four-body continuum channels $A + A + A + B$.

For the $A_3 + B$ channels, we use ($\alpha=0$) [9]

$$\Phi_0^{(3)}(\Omega_3) = \sum_{l=1}^3 \frac{2 \sinh(s_0 \alpha_3^{(l)})}{\sin(2\alpha_3^{(l)})} \quad (7)$$

$$(T_{\Omega_3} + V_{123}) \Phi_0^{(3)} = -\frac{s_0^2 + \frac{1}{4}}{2\mu_3 R_3^2} \Phi_0^{(3)} \quad (8)$$

where the summation is over the three possible three-body Jacobi sets, each with its own Delves' hyperangle $\alpha_3^{(l)}$; $s_0 \approx 1.0062$ is a universal constant. Substituting Eq. (7) into Eq. (6), and the result into Eq. (5), gives the equation for the bound trimer channels:

$$\left(-\frac{\partial^2}{\partial \alpha_4^2} - \frac{s_0^2 + \frac{1}{4}}{\sin^2 \alpha_4} \right) u_{0n} = \lambda_{0n}^2 u_{0n}, \quad U_{0n} = \frac{\lambda_{0n}^2 - \frac{1}{4}}{2\mu_4 R_4^2}. \quad (9)$$

The physically acceptable solution of Eq. (9) is

$$u_{0n}(R_4; \alpha_4) = N_4 \cos \alpha_4 \sin^{\frac{1}{2} + is_0}(\alpha_4) \times {}_2F_1\left(\frac{3}{4} + \frac{is_0}{2} - \frac{\lambda_{0n}}{2}, \frac{3}{4} + \frac{is_0}{2} + \frac{\lambda_{0n}}{2}; \frac{3}{2}; \cos^2 \alpha_4\right) \quad (10)$$

with N_4 the normalization constant. To avoid the Thomas collapse [26], we take the simple and expedient strategy of requiring that the three-body hyperradial wave functions vanish for $R_3 \leq R_0$, yielding a boundary condition on u_{0n} : $u_{0n}(\alpha_4 \leq \arcsin[\sqrt{\mu_3/\mu_4} R_0/R_4]) = 0$. We note that none of our conclusions will depend on the details of this regularization — R_0 merely sets the scale for the features we predict. Imposing this boundary condition leads to a transcendental equation for λ_{0n} , and it can be shown explicitly that the Efimov trimer energies are recovered from U_{0n} in the limit $R_4 \rightarrow \infty$. We include the diagonal coupling $Q_{\nu\nu} = \left\langle \frac{d\Phi_\nu}{dR_4} \middle| \frac{d\Phi_\nu}{dR_4} \right\rangle$ to get the most physical adiabatic potentials $W_\nu(R_4) = U_\nu(R_4) - \frac{1}{2\mu_4} Q_{\nu\nu}(R_4)$. For $W_\nu(R_4) > 0$ and $R_4 \gg R_0$,

$$W_\nu(R_4) \approx \left[\frac{2(n+\gamma) - s_0}{\pi} + \frac{1}{2} - \frac{s_0}{\pi} \ln \left(\frac{\mu_4 R_4^2}{\mu_3 R_0^2} \right) \right] \frac{1}{2\mu_4 R_4^2}. \quad (11)$$

Here, $\gamma = 0.30103$ and $n = 1, 2, 3, \dots$ labels the trimer states.

We follow the same logic for the four-body continuum channels $A + A + A + B$. The only difference is that $\Phi_\alpha^{(3)}$ is now a three-body continuum function, but still for $|a_{AA}| \rightarrow \infty$. That is, we replace s_0 in Eqs. (7)–(10) by is_α ($\alpha > 0$), where s_α are real numbers determined by

$$\sqrt{3} s_\alpha \cos\left(\frac{\pi}{2} s_\alpha\right) = 8 \sin\left(\frac{\pi}{6} s_\alpha\right). \quad (12)$$

The resulting $u_{\alpha m}$ satisfy the same boundary condition at R_0 as the bound channels. Asymptotically, $\lambda_{\alpha m} \rightarrow s_\alpha + 2m + \frac{3}{2}$ with $m = 0, 1, 2, \dots$ labeling the four-body continuum states possible for each α . The four-body continuum potentials thus behave as $1/R_4^2$ for $R_4 \gg R_0$.

If we expand the total four-body wave function as

$$\Psi(R_4, \Omega_4, \Omega_3) = \sum_\nu F_\nu(R_4) \Phi_\nu^{(4)}(R_4; \Omega_4, \Omega_3), \quad (13)$$

FIG. 2: (color online) The lowest four-body adiabatic hyperspherical potentials W_ν multiplied by $2\mu_4 R_4^2$ to better show their behavior. Black solid lines denote atom-trimer potentials for $\alpha=0$ and $n=1,2,3,4$; blue dashed lines, four-body continuum potentials for $\alpha=1$ ($s_1=4.465$) and $m=0,1,2$; and the red dotted line, the four-body continuum potential with $\alpha=2$ ($s_2=6.818$) and $m=0$. We take $R_0=10$ a.u. for all curves.

then the non-adiabatic couplings between four-body continuum and atom-trimer channels vanish since $\Phi_\alpha^{(3)}$ are independent of R_3 and form an orthonormal set. Recombination is thus driven only by the diabatic couplings

$$V_{\nu'\nu} = \langle \nu' | V_{AB}(\mathbf{r}_{14}) + V_{AB}(\mathbf{r}_{24}) + V_{AB}(\mathbf{r}_{34}) | \nu \rangle \quad (14)$$

and occurs predominantly at the crossings in Fig. 2. Figure 2 shows the lowest atom-trimer and four-body continuum potentials. Notice that the two sets of potentials cross in several places. The lowest two atom-trimer potentials, however, do not cross a continuum channel. In our model, then, the lowest two Efimov trimers can only be populated by weak non-adiabatic transitions between atom-trimer channels. This conclusion is independent of R_0 , but for more realistic, finite range two-body potentials all the channels will likely be coupled at small R_4 .

Using Eq. (2) and evaluating $V_{\nu\nu}$ numerically, we find that it is proportional to R_4^{-3} when $R_4 \lesssim |a_{AB}|$. But, four-body recombination should occur when R_4 is comparable to the size of the final three-body Efimov state. So, by making $|a_{AB}|$ small compared with the size of the state we are interested in, we can neglect $V_{\nu\nu}$. This requirement must be balanced against the need to have large off-diagonal coupling elements $V_{\nu'\nu}$, although there will be transitions so long as a_{AB} is not zero.

In the adiabatic hyperspherical representation, four-body recombination Eq. (1) starts on a four-body continuum channel at $R_4 \rightarrow \infty$. As the atoms collide, they encounter an infinite number of crossings with atom-trimer channels, one for each Efimov state, before reaching the classical turning point. Treating each crossing as independent from the others, we can estimate the transition probability using

the Landau-Zener approximation if $E > W_\nu(R_4^c)$, where $R_4^c \approx R_0 \sqrt{\frac{\mu_3}{\mu_4}} \exp\left[\frac{\pi}{s_0} \left(n - \frac{1}{2}\lambda_\nu^c + \frac{2\gamma - s_0}{2\pi} + \frac{1}{4}\right)\right]$ is the position of the crossing. In this approximation, the recombination probability is given by $P_{LZ} = 4T(1-T)\cos^2\Delta\phi$. The relative phase $\Delta\phi$ is approximately zero since the potentials are nearly parallel near the crossings, and T is

$$T = \exp\left[-\sqrt{\frac{\mu_3}{\mu_4}} \left(\frac{\mu_3}{\mu_{AB}} \frac{a_{AB}}{R_4^c}\right)^2 \frac{\beta^2}{k_\nu^c R_0} \frac{2\pi}{(2\frac{s_0}{\pi}\lambda_\nu^c + \frac{1}{4})}\right],$$

with k_ν^c the wavevector and $\lambda_\nu^c \approx \sqrt{(s_\alpha + 2m + \frac{3}{2})^2 - \frac{1}{4}}$ the eigenvalue of Eq. (9) — both evaluated at the crossing. The unitless constant β originates from the evaluation of $V_{\nu'\nu}$, has a weak dependence on the channel numbers, and is on the order of 10^{-3} . If $E < W_\nu(R_4^c)$, the system must tunnel in the initial continuum potential to reach the crossing and make a transition. Figure 2 and R_4^c show that in this case, though, there is always another energetically accessible crossing at larger R_4 that will dominate the recombination. Consequently, we set $P_{LZ} = 0$ for all energetically closed crossings since they do not alter the peak structure of the total recombination probability. Further, we expect the first open crossing beyond the classical turning point to dominate all other open crossings since the kinetic energy grows with R_4 , ensuring subsequent crossings will be traversed diabatically (i.e. without a transition). For the same reason, we neglect the possibility of transitions from an atom-trimer channel back to the four-body continuum at $R_4 > R_4^c$.

The four-body recombination rate K_4 is related to P_{LZ} by $K_4 \propto \frac{P_{LZ}}{k}$ where $k = \sqrt{2\mu_4 E}$ is the incident four-body wave vector. Because the couplings $V_{\nu'\nu}$ are quite small, the peaks of P_{LZ} occur at $E \approx W_\nu(R_4^c)$,

$$W_\nu(R_4^c) \approx \frac{(s_\alpha + 2m + \frac{3}{2})^2}{2\mu_{3,4}R_0^2} e^{-\frac{\pi}{s_0}(2n - s_\alpha - 2m + \frac{2\gamma - s_0}{\pi} - 1)}.$$

This expression shows that for a given initial channel (s_α, m) there is a geometrically spaced sequence of peaks in energy for recombination to Efimov trimers. This characteristic feature of the three-body Efimov physics thus comes through in the four-body physics as well. Moreover, the spacing of the features is $\exp(-2\pi/s_0)$ just as one would predict from the three-body physics. To illustrate this point, we show in Fig. 3 the total recombination probability P_T calculated as a sum of P_{LZ} over all initial and final channels. Note that the width of the peaks increases with $|a_{AB}|$ as does their shift from $W_\nu(R_4^c)$.

Up to this point, our analysis has assumed $|a_{AA}| = \infty$. If we let it be finite instead, then the above analysis applies in the regime $|a_{AA}| \gg |a_{AB}|$. To avoid the complication of a $A_2^* + A + B$ continuum degenerate with the channels of interest, we further require $a_{AA} < 0$ so that there are no weakly bound dimers. Under these conditions, the four-body adiabatic potentials behave as described above

FIG. 3: The total recombination probability P_T for atom-trimer channels up to $n=6$. (s_α, m) labels the incident channel that contributes to the indicated peak. We have taken $R_0=10$ a.u. and $a_{AB}=100$ a.u..

in the region $|a_{AB}| \ll R_4 \ll |a_{AA}|$. For $R_4 \gg |a_{AA}|$, the four-body continuum potentials approach the four-body hyperspherical harmonic potentials $W_\nu \approx \frac{\lambda(\lambda+7)+12}{2\mu_4 R_4^2}$ with λ a non-negative integer, and the atom-trimer potentials approach the trimer bound energies $W_\nu \approx E_n$. It follows that at energies $(2\mu_4 a_{AA}^2)^{-1} \ll E \ll (2\mu_4 a_{AB}^2)^{-1}$ K_4 keeps the structure described above.

It is in the zero energy limit that the effects of finite a_{AA} reveal themselves, and we will use WKB to explore this limit [13]. When $E \rightarrow 0$, recombination into the most weakly bound Efimov trimer dominates. Since the size of this trimer is on the order of $|a_{AA}|$, we expect recombination to occur at $R_4 \approx |a_{AA}|$. So, following an analysis similar to that described in Ref. [13], we find that the recombination probability is

$$P \propto (k|a_{AA}|)^7 \sin^2(k_n|a_{AA}| + \Phi), \quad (15)$$

where Φ is a short-range phase independent of a_{AA} and $k_n = \frac{2}{R_0} \frac{\mu_4}{\mu_3} \exp[-(n\pi + \gamma)/s_0]$ is the wave number for the final trimer state n at $E=0$. When $|a_{AA}|$ increases by a factor of 22.7, a new atom-trimer channel appears and k_n changes to k_{n+1} which, in turn, changes the period of the a_{AA} -dependent oscillations. It turns out that recombination into a particular atom-trimer state will show about seven full oscillations in K_4 as a function of a_{AA} . From the relation $K_4 \propto P/k^7$, Eq. (15) also shows that K_4 will be constant in the threshold regime, $E \lesssim (2\mu_4 a_{AA}^2)^{-1}$.

If the trimers cannot be experimentally observed directly, then their production can be monitored through the loss of either A or B atoms. In an ultracold mixture of the two, it is much better to monitor the B atoms, however, as other few-body processes will lead to loss of A atoms and thus mask the effects we predict. The best scenario makes the B atoms spin-polarized fermions. In this case, $A+A+A+B$ recombination is unaffected, but the competing loss processes involving two or more B atoms

can be completely avoided as they will be suppressed near threshold [25]. There remains the possibility for loss of B atoms in $A+A+B$ collisions, but for $|a_{AA}|=\infty$ or a_{AA} finite but negative, the three-body potentials are all repulsive [27] and only deeply-bound dimer channels are available. The various loss rates for this system are thus small [27]. Monitoring the loss of B atoms should then provide a signature of Efimov trimer formation.

To summarize, we have taken the first steps in understanding ultracold four-body recombination into Efimov trimers. By carefully setting up the problem, we were able to obtain largely analytical results. In the process, we showed that the four-body recombination should show prominent, geometrically spaced peaks that reflect the three-body Efimov physics. In fact, these peaks are separated by precisely the factor one expects from the three-body physics. We also suggested one approach for experimentally determining whether four-body recombination was indeed occurring. Should an experiment reach this milestone, then our work further suggests the interesting possibility that one might be able to use the temperature to control which Efimov state is produced.

We are grateful to J.P. D'Incao for early discussions of this work. This work was supported in part by the National Science Foundation and in part by the Air Force Office of Scientific Research.
